15 **Abstract**

16 Understanding why some clades have evolved to be more phenotypically
17 diverse than others remains a central challenge in evolutionary biology.
18 This issue is particularly relevant when we consider whether a group of
19 species exhibits the characteristics of an adaptive radiation. However, we
20 must be able to identify exceptionally diverse clades before we can
21 determine the selective pressures which led to the evolution of their
22 variety. Tenrecs (Afrosoricida, Tenrecidae) are a family of small mammals
23 which is often cited as an example of a phenotypically diverse, adaptively
24 radiated group. However, this assumption has not been tested previously.
25 Here we use geometric morphometric analyses of cranial and mandible
26 shape to test whether tenrecs show exceptional morphological disparity.
27 We find that tenrecs are no more morphologically diverse than their sister
28 taxa, the golden moles (Afrosoricida, Chrysochloridae), casting doubt over
29 whether tenrecs should be considered to be an exceptionally diverse
30 group. Our results reveal new insight into patterns of morphological
31 variety within tenrecs and the question of whether apparent phenotypic
32 diversity is more than skin deep.

33 Introduction

34 Phenotypically diverse groups have long attracted the attentions of
35 evolutionary biologists. Studies which quantify phenotypic variety (e.g.
36 Price et al., 2013; Collar et al., 2011; Brusatte et al., 2008) have important
37 implications for understanding the factors that contribute to high
38 morphological diversity in some groups and not others (Losos & Mahler,
39 2010).

40 These approaches are particularly relevant when it comes to the study
41 of adaptive radiations: "evolutionary divergence of members of a single
42 phylogenetic lineage into a variety of different adaptive forms" (Futuyma
43 1998, cited by Losos, 2010). There are many famous examples of
44 adaptively radiated groups including Darwin's finches, Caribbean *Anolis*
45 lizards and cichlid fish (Gavrilets & Losos, 2009). However, there has been
46 considerable debate about how adaptive radiations should be defined
47 (Glor, 2010; Losos & Mahler, 2010) based on the relative importance of
48 speciation rate, species richness and morphological diversity. One
49 particular issue is whether it is even meaningful to classify a specific
50 group of species as an adaptive radiation or not since any classification
51 relies on arbitrary distinctions between what are most likely a continua of
52 characteristics which describe the diversity of a particular clade (Olson &
53 Arroyo-Santos, 2009).

54 However, despite the controversies and disagreements, there does
55 seem to be a consensus that high morphological diversity is an important
56 criterion for identifying a group of species as belonging on the adaptive
57 radiation scale (Losos & Mahler, 2010; Olson & Arroyo-Santos, 2009). One
58 way to test whether a group shows high morphological diversity is

59 through sister taxa comparisons. For example, Losos and Miles (2002)
60 used this approach to demonstrate exceptional diversity in some but not
61 all clades of iguanid lizards. Here we use sister-taxa comparisons to test
62 whether tenrecs (Afrosoricida, Tenrecidae) exhibit the high levels of
63 phenotypic diversity that are expected of an adaptively radiated clade.

64 The tenrec family is comprised of 34 species, 31 of which are endemic
65 to Madagascar (Olson, 2013). From a single common ancestor (Asher &
66 Hofreiter, 2006), Malagasy tenrecs diversified into a wide variety of
67 descendant species which convergently resemble distantly related
68 insectivore mammals such as shrews (*Microgale* tenrecs), moles
69 (*Oryzorictes* tenrecs) and hedgehogs (*Echinops* and *Setifer* tenrecs)
70 (Eisenberg & Gould, 1969). These convergent resemblances are so great
71 that tenrecs used to be considered part of the general "insectivore" clade
72 and only molecular studies revealed their true phylogenetic affinities
73 within the Afrotherian mammals (Stanhope et al., 1998).

74 Tenrecs are often cited as an example of an adaptively radiated family
75 which exhibits exceptional morphological diversity (Soarimalala &
76 Goodman, 2011; Olson & Goodman, 2003; Eisenberg & Gould, 1969).
77 However, evidence for claim has not been tested. Here we present the first
78 quantitative test of patterns of phenotypic diversity in tenrecs and
79 examine how morphological diversity in tenrecs compares to their closest
80 relatives, the golden moles (Afrosoricida, Chrysochloridae).

81 We use disparity, the diversity of organic form (Foote, 1997; Wills et al.,
82 1994; Erwin, 2007), to measure phenotypic variety within the two families.
83 Disparity can be calculated in many ways including measures of
84 morphospace occupation (e.g. Goswami et al., 2011; Brusatte et al., 2008)

85 and rate-based approaches that assess the amount of directed change
86 away from an ancestor (O'Meara et al., 2006; Price et al., 2013). Here we
87 focus on patterns of phenotypic variety in extant species rather than
88 analysing the rate of diversity accumulation through time. Using the most
89 complete morphological data set of tenrecs and golden moles to date we
90 apply two dimensional geometric morphometrics (Rohlf & Marcus, 1993;
91 Adams et al., 2013) to quantify variation in cranial and mandible
92 morphologies as proxies for phenotypic diversity in the two families.

93 Our results indicate an overall trend of higher morphological diversity
94 in tenrec compared to golden mole crania. However these differences are
95 not statistically significant, indicating that, with regards to cranial shape,
96 tenrecs are not as phenotypically diverse as is often assumed. In contrast,
97 we found significantly greater morphological disparity in golden mole
98 mandibles compared to tenrecs, seemingly due to more variable posterior
99 mandible morphologies in golden moles.

100 These findings cast doubt over whether the apparent phenotypic
101 diversity within tenrecs should be considered to be truly exceptional.

102 **Materials and Methods**

103 **Morphological data collection**

104 One of us (SF) photographed cranial specimens of tenrecs and golden
105 moles at the Natural History Museum London (NHML), the Smithsonian
106 Institute Natural History Museum (SI), the American Museum of Natural
107 History (AMNH), Harvard's Museum of Comparative Zoology (MCZ)
108 and the Field Museum of Natural History, Chicago (FMNH). We

109 photographed the specimens with a Canon EOS 650D camera fitted with
110 an EF 100mm f/2.8 Macro USM lens using a standardised procedure to
111 minimise potential error (see supplementary material for details).

112 We collected pictures of the skulls in dorsal, ventral and lateral views
113 (right side of the skull) and of the outer (buccal) side of the right
114 mandibles. A full list of museum accession numbers and details for how
115 to access the images can be found in the supplementary material.

116 In total we collected pictures from 182 skulls in dorsal view (148
117 tenrecs and 34 golden moles), 173 skulls in ventral view (141 tenrecs and
118 32 golden moles), 171 skulls in lateral view (140 tenrecs and 31 golden
119 moles) and 182 mandibles in lateral view (147 tenrecs and 35 golden
120 moles), representing 31 species of tenrec (out of the total 34 in the family)
121 and 12 species of golden moles (out of a total of 21 in the family (Asher
122 et al., 2010)). We used the taxonomy of Wilson and Reeder (2005)
123 supplemented with more recent sources (IUCN, 2012; Olson, 2013) to
124 identify our specimens.

125 We used a combination of both landmarks (type 2 and type 3,
126 (Zelditch et al., 2012)) and semilandmarks to characterise the shapes of
127 our specimens. Figure 1 shows our landmarks (points) and
128 semilandmarks (outline curves) for the skulls in dorsal and ventral views
129 and figure 2 shows the points and curves we used for lateral views of
130 skulls and mandibles. Corresponding definitions of each of the landmarks
131 can be found in the supplementary material.

132 We digitised all landmarks and semilandmarks in tpsDIG, version 2.17
133 (Rohlf, 2013). We re-sampled the outlines to the minimum number of
134 evenly spaced semilandmark points required to represent each outline

135 accurately (MacLeod, 2013, details in supplementary material). We used
136 TPSUtil (Rohlf, 2012) to create sliders files (Zelditch et al., 2012) to define
137 which points were semilandmarks. We conducted all subsequent analyses
138 in R version 3.0.2 (R Core Team, 2014) within the geomorph package
139 (Adams et al., 2013). We used the gpagen function to run a general
140 Procrustes alignment (Rohlf & Marcus, 1993) of the landmark coordinates
141 while sliding the semilandmarks by minimising procrustes distance
142 (Bookstein, 1997). We used these Procrustes-aligned coordinates of all
143 species to calculate average shape values for each species (n=43) which we
144 then used for a principal components (PC) analysis with the
145 plotTangentSpace function (Adams et al., 2013).

146 **Disparity calculations**

147 We calculated morphological disparity separately for golden moles and
148 tenrecs in each of the morphological datasets. We used the PC axes which
149 accounted for 95% of the cumulative variation to calculate four disparity
150 metrics; the sum and product of the range and variance of morphospace
151 occupied by each family (Brusatte et al., 2008; Foth et al., 2012; Ruta et al.,
152 2013). We also calculated morphological disparity directly from the
153 Procrustes-superimposed shape data based on the sum of the squared
154 inter-landmark distances between the average shape of a species and the
155 overall grand mean shape (SSqDist, Zelditch et al., 2012).

156 We used two approaches to test whether tenrecs have significantly
157 different morphologies compared to golden moles. The first was a
158 comparison of morphospace occupation between the two groups with non
159 parametric MANOVAs (Anderson, 2001) to test whether tenrecs and

160 golden moles occupy significantly different areas of morphospace (e.g
161 Serb et al., 2011; Ruta et al., 2013).

162 Secondly, we used pairwise permutation tests to test the null
163 hypothesis that tenrecs and golden moles have equal disparity. If this
164 hypothesis were true then the designation of each species as belonging to
165 either tenrecs or golden moles should be arbitrary. Therefore we
166 permuted the data by assigning family identities at random to each
167 specimen and calculated the differences in disparity for each of the new
168 family groupings. We repeated these permutations 1000 times to generate
169 a null distribution of the expected differences in family disparity. We
170 compared our observed (true) measures of the differences in disparity
171 between tenrecs and golden moles to these permuted distributions to
172 test whether the families had significantly different levels of disparity.

173 The majority of tenrec species (19 out of 31 in our data) are members
174 of the *Microgale* (shrew-like) genus which is notable for its relatively low
175 phenotypic diversity (Soarimalala & Goodman, 2011; Jenkins, 2003). The
176 strong similarities among these species may mask signals of higher
177 disparity among other tenrecs. Therefore we repeated our family-level
178 comparisons of disparity with a reduced data set that excluded the
179 *Microgale* so that we could compare disparity within the remaining 12
180 tenrec species to disparity within the 12 species of golden moles.

Results

Morphological disparity in tenrecs and golden moles

Figure 3 depicts the morphospace plots derived from our principal components analyses of average Procrustes-superimposed shape coordinates for each species in our skull and mandible data respectively. We used the principal components axes which accounted for 95% of the cumulative variation ($n = 7, 8, 8$ axes for the dorsal, ventral and lateral skull analyses respectively and $n = 12$ axes for the mandibles) to calculate the disparity of each family.

Tenrecs and golden moles clearly have very different cranial and mandible morphologies: in each analysis, the families occupy significantly different areas of morphospace (npMANOVA, table 3). Our comparisons of disparity levels within each family yielded different trends for the skulls compared to the mandible analyses.

In our analyses of the three different views of the skulls, when disparity is calculated from principal component - based metrics there is an overall trend for tenrecs to have higher disparity than golden moles. However, none of these differences are statistically significant (table 1).

In contrast, when we calculated disparity based on the squared inter-landmark distances between the average shape of a species and the overall grand mean shape (Zelditch et al., 2012) then golden moles had significantly higher levels of disparity than tenrecs (table 1). These results indicate that golden moles are more distant from the overall mean shape in each of the analyses (farther from the (0,0) points in the PCA plots figure 3) which makes intuitive sense given that the overall meanshape in

206 each analysis will necessarily be biased towards the more species-rich
207 tenrec family.

208 There is a less clear pattern from our analysis of disparity in the
209 mandibles. Three of our five metrics indicate that golden moles have
210 significantly higher disparity in the shape of their mandibles than tenrecs
211 (table 1) although one metric (sum of ranges) indicated the opposite result.

212 The three curves at the back of the mandibles (figure 2) place a
213 particular emphasis on shape variation in the posterior of the bone; the
214 ramus, coronoid, condylar and angular processes. Therefore, higher
215 disparity in golden mole mandibles compared to tenrecs could be driven
216 by greater morphological variation in these structures. To test this idea,
217 we repeated our morphometric analyses of the mandibles with a reduced
218 data set of points; just the seven landmark points and one single curve at
219 the base of the jaw between landmarks 1 and 7 (figure 2). When we
220 compared familial disparity levels with this reduced data set we found
221 that golden moles no longer had significantly higher disparity than
222 tenrecs in the principal components-based metrics (table 1).

223 **Morphological disparity in non-*Microgale* tenrecs and** 224 **golden moles**

225 We repeated our disparity comparisons with a subset of the tenrec
226 specimens to remove the large and phenotypically similar *Microgale* tenrec
227 genus. In this case we found that tenrecs have significantly higher
228 disparity than golden moles when the skulls are analysed in lateral view
229 (table 2). However, none of the other comparisons in any of the analyses
230 were significant. Similarly, the trend in the main analysis for golden moles

231 to have significantly higher disparity measured as the sum of squared
232 inter-landmark distances between the average shape of a species and the
233 overall grand mean shape (table 1) was not repeated in this comparison of
234 disparity in non-*Microgale* tenrecs and golden moles (table 2).

235 Discussion

236 Our analyses are the first quantitative investigation of morphological
237 disparity in tenrecs. Our results suggest that phenotypic variation in
238 tenrecs is not as exceptional as it first appears.

239 When we compared tenrecs' cranial morphologies to their closest
240 relatives we found a trend towards higher disparity in tenrecs than in
241 golden moles but none of these differences were significant. Even when
242 we removed the phenotypically similar *Microgale* genus, tenrecs were still
243 no more diverse than golden moles in most of the analyses (table 2). In
244 contrast, our analyses of the mandibles indicated that golden moles have
245 more disparate mandible shapes than tenrecs seemingly due to greater
246 diversity within their posterior-mandible shapes.

247 It is evident that tenrecs are a diverse group, both phenotypically and
248 ecologically. Body sizes of extant tenrecs span three orders of magnitude
249 (2.5 to > 2,000g) which is a greater range than all other Families, and most
250 Orders, of living mammals (Olson & Goodman, 2003). Within this vast
251 size range there is striking phenotypic diversity from the spiny *Echinops*,
252 *Setifer* and *Hemicentetes* to the mole-like *Oryzorictes* and shrew-like
253 *Microgale*. These diverse forms inhabit a wide variety of ecological niches
254 and habitats including terrestrial, arboreal, semi-aquatic and

255 semi-fossorial environments (Soarimalala & Goodman, 2011). In contrast,
256 although golden moles occupy a wide altitudinal, climatic and
257 vegetational spectrum of habitats (Bronner, 1995), they are all fossorial
258 species which, superficially at least, appear to be less phenotypically
259 diverse than tenrecs.

260 There is a danger when using sister taxa comparisons that a clade's
261 diversity will be judged to be exceptional just because it is more variable
262 than an exceptionally non-diverse sister taxa (Losos & Miles, 2002).
263 However, we compared an apparently phenotypically diverse clade to a
264 more uniform sister taxa yet our results do not indicate that tenrecs are
265 more morphologically diverse than their closest relatives (table 1). These
266 unexpected findings highlight the importance of testing our subjective
267 assumptions about patterns of morphological variety.

268 One apparent anomaly in our results is that we found opposite
269 patterns of group dissimilarities in the analyses of skulls and mandibles.
270 Our landmarks and curves for the mandibles (figure 2) include aspects of
271 variation in the dentition but they focus particular attention on the
272 ascending ramus (condyloid, condylar and angular processes). Therefore
273 higher disparity in golden moles could reflect greater morphological
274 variability in these posterior mandible structures. To test this idea we
275 deleted the three semi-landmark curves around these structures and
276 repeated our disparity analyses of mandibles using seven landmarks and
277 just one curve at the base of the jaw. In this case we retrieved the opposite
278 pattern than previously: tenrecs had higher morphological disparity than
279 golden moles but these patterns were not significant (see supplementary
280 material). Therefore, our results indicate that golden moles have greater
281 morphological variation in the posterior structures of their mandibles

282 compared to tenrecs.

283 It proved impossible to position reliable landmarks on the
284 corresponding mandibular articulation areas of the skull in lateral view
285 (see supplementary). Therefore we could not test whether higher
286 morphological disparity in the rami were correlated with associated
287 morphological variety in the articulation areas of the skull.

288 We focused on variation in cranial morphology which is commonly
289 used to study phenotypic variation within species (Blagojević &
290 Milošević-Zlatanović, 2011; Bornholdt et al., 2008), to delineate species
291 boundaries within a clade (e.g. Panchetti et al., 2008) or for
292 cross-taxonomic comparative studies of phenotypic (dis)similarities (e.g.
293 Ruta et al., 2013; Goswami et al., 2011; Wroe & Milne, 2007). However,
294 studies of morphological disparity are inevitably constrained to measure
295 diversity within specific traits rather than overall phenotypes (Roy &
296 Foote, 1997). Disparity calculations based on skull shape can yield similar
297 results compared to analyses of whole-skeleton discrete characters and
298 limb proportion data sets (Foth et al., 2012). However, we would need to
299 extend our analyses to other morphological proxies of phenotype to test
300 whether the cranial morphological disparity patterns presented here are
301 indicative of overall differences in phenotypic diversity in tenrecs and
302 golden moles.

303 Evidence of exceptional morphological diversity is one criterion for
304 designating a clade as an adaptive radiation (Losos & Mahler, 2010) and
305 our analyses are the first measures of morphological diversity within
306 tenrecs, a group which is commonly cited as an example of an adaptive
307 radiation (Olson, 2013). However, describing phenotypic divergence as the

308 product of an adaptive radiation requires exceptional morphological
309 diversity in traits which have specific and proven adaptive significance
310 (Losos & Mahler, 2010).

311 The evolution of cranial shape (both upper skull and mandible),
312 particularly dental morphology, has obvious correlations with dietary
313 specialisations and occupation of specific ecological niches (e.g. Wroe &
314 Milne, 2007). Considering the wide ecological diversity of our study
315 species; semi-fossorial, arboreal, terrestrial and semi-aquatic (Soarimalala
316 & Goodman, 2011), we think that it is reasonable to expect that this
317 variety should be reflected in skull morphology.

318 However, we have not included any measures of the "adaptiveness" of
319 cranial shape in our analyses and therefore our analyses should not be
320 considered to be an explicit test of whether or not tenrecs are an adaptive
321 radiation (Losos & Mahler, 2010). Instead we have made the first step
322 towards understanding the apparent phenotypic diversity within tenrecs
323 within a quantitative framework. Future work should focus on explicit
324 measures of the "adaptiveness" and functional importance of tenrec
325 cranial and post-cranial morphologies to understand the significance of
326 morphological diversity within the family (e.g. Mahler et al., 2010).

327 We have presented the first quantitative study which tests the common
328 claim that tenrecs are an exceptionally diverse group (Olson, 2013;
329 Soarimalala & Goodman, 2011; Eisenberg & Gould, 1969). Focusing on
330 cranial diversity is only one aspect of morphological variation and further
331 analyses are required to test whether other morphological traits yield
332 similar patterns. However, our current results provide a clear indication
333 that phenotypic variety within tenrecs is perhaps not as exceptional as it

334 first seems.

458 **List of Figures**

| | | | |
|-----|---|--|----|
| 459 | 1 | Diagram of the landmarks and curves for the skulls in dorsal | |
| 460 | | and ventral views | 22 |
| 461 | 2 | Diagrams of the landmarks and curves used for lateral views | |
| 462 | | of skulls and mandibles | 23 |
| 463 | 3 | Principal components plots of the morphospaces occupied | |
| 464 | | by tenrecs and golden moles | 24 |

Figure 1: Landmarks (red points) and curves (blue lines) used to capture the morphological shape of skulls in dorsal and ventral views respectively. Curves were re-sampled to the same number of evenly-spaced points. Descriptions of the curves and landmarks are in the supplementary material. The specimens belong to two different *Potamogale velox* (Tenrecidae) skulls: accession number AMNH 51327 for the dorsal picture and NHML 1934.6.16.2 for the ventral picture

Figure 2: Landmarks (red points) and curves (blue lines) used to capture the morphological shape of lateral views of skulls and mandibles respectively. Curves were re-sampled to the same number of evenly-spaced points. Descriptions of the curves and landmarks are in the supplementary material. The specimens belong to two different *Potamogale velox* (Tenrecidae) skulls: accession number AMNH 51327 for the dorsal picture and NHML 1934.6.16.2 for the ventral picture

Figure 3: Principal components plots of the morphospaces occupied by tenrecs (red, n=31 species) and golden moles (black, n=12) for the skulls: dorsal (A), ventral (B), lateral (C) and mandibles (D) analyses. Axes are PC1 and PC2 of the average scores from a PCA analysis of mean Procrustes shape coordinates for each species.

465 List of Tables

| | | | |
|-----|---|--|----|
| 466 | 1 | Summary of disparity comparisons between tenrecs and golden | |
| 467 | | moles | 26 |
| 468 | 2 | Summary of disparity comparisons between non- <i>Microgale</i> | |
| 469 | | tenrecs and golden moles | 27 |
| 470 | 3 | Summary of npMANOVA comparisons of morphospace oc- | |
| 471 | | cupation for tenrecs and golden moles | 28 |

Table 1: Summary of disparity comparisons between tenrecs (T) and golden moles (G) for each of our data sets(rows) and five disparity metrics (columns). "Mandibles:one curve" refers to our shape analysis of mandibles excluding the three curves around the posterior structures of the jaw (figure 2). Significant differences are highlighted in bold with the corresponding p value in brackets. Disparity metrics are; sum of variance, product of variance, sum of ranges, product of ranges and sum of squared distances among species and the overall mean shape.

| Disparity metric | SumVar | ProdVar | SumRange | ProdRange | SSqDist |
|-------------------------|---------------|------------------------|------------------------|------------------------|--------------------|
| Skulls dorsal | T>G | T>G | T>G | T>G | G>T* (o) |
| Skulls lateral | T>G | T>G | T>G | T>G | G>T* (o) |
| Skulls ventral | T>G | G>T | T>G | T>G | G>T* (o) |
| Mandibles | G>T | G>T* (0.008) | T>G* (0.025) | T>G* (0.009) | T>G* (o) |
| Mandibles | G>T | G>T | T>G | T>G | T>G* (o) |

Table 2: Summary of disparity comparisons between non-*Microgale* tenrecs (T) and golden moles (G) for each of our data sets(rows) and five disparity metrics (columns). Significant differences are highlighted in bold with the corresponding p value in brackets. Disparity metrics are; sum of variance, product of variance, sum of ranges, product of ranges and sum of squared distances among species and the overall mean shape.

| Disparity metric | SumVar | ProdVar | SumRange | ProdRange | SSqDist |
|------------------|--------------|---------|------------------------|-----------------------|------------------------|
| Skulls dorsal | T>G | T>G | T>G | T>G | T>G |
| Skulls lateral | T>G* (0.014) | T>G | T>G* (0.001) | T>G*(0.003) | G>T* (0.014) |
| Skulls ventral | T>G | T>G | T>G | T>G | T>G |
| Mandibles | T>G | G>T | T>G | G>T | G>T |

Table 3: Summary of the npMANOVA comparisons of morphospace occupation for tenrecs and golden moles in each of the four analyses (three views of skulls and mandibles). In each case the two families occupy significantly different areas of morphospace.

| Analysis | F | R² | p value |
|-----------------|----------|----------------------|----------------|
| Skulls dorsal | 66.02 | 0.62 | 0.001 |
| Skulls ventral | 100.74 | 0.71 | 0.001 |
| Skulls lateral | 75.07 | 0.65 | 0.001 |
| Mandibles | 59.34 | 0.59 | 0.001 |
