## <sup>13</sup> **Abstract**

## 14 Introduction

15 Phenotypically diverse groups have long attracted the attentions of  
16 evolutionary biologists. Studies which quantify phenotypic variety (e.g.  
17 Price et al., 2013; Collar et al., 2011; Brusatte et al., 2008) have important  
18 implications for understanding the factors that contribute to high  
19 morphological diversity in some groups and not others (Losos & Mahler,  
20 2010).

21 These approaches are particularly relevant when it comes to the study  
22 of adaptive radiations: "evolutionary divergence of members of a single  
23 phylogenetic lineage into a variety of different adaptive forms" (Futuyma  
24 1998, cited by Losos, 2010). There are many famous examples of  
25 adaptively radiated groups (Gavrilets & Losos, 2009). However, there has  
26 also been considerable debate about how adaptive radiations should be  
27 defined (Glor, 2010; Losos & Mahler, 2010) based on the relative  
28 importance of speciation rate, species richness and morphological  
29 diversity. One particular issue is whether it is even meaningful to classify  
30 a specific group of species as an adaptive radiation or not since any  
31 classification relies on arbitrary distinctions between what are most likely  
32 a continua of characteristics which describe the diversity of a particular  
33 clade (Olson & Arroyo-Santos, 2009).

34 However, despite the controversies and disagreements, there does  
35 seem to be a consensus that high morphological diversity is an important  
36 criterion for identifying a group of species as belonging on the adaptive  
37 radiation scale (Losos & Mahler, 2010; Olson & Arroyo-Santos, 2009). One  
38 way to test whether a group shows high morphological diversity is  
39 through sister taxa comparisons. For example, Losos and Miles (2002)

40 used this approach to demonstrate exceptional diversity in some but not  
41 all clades of iguanid lizards. Here we use sister-taxa comparisons to test  
42 whether tenrecs (Afrosoricida, Tenrecidae) exhibit the high levels of  
43 phenotypic diversity that are expected of an adaptively radiated clade.

44 The tenrec family is comprised of 34 species, 31 of which are endemic  
45 to Madagascar (Olson, 2013). From a single common ancestor (Asher &  
46 Hofreiter, 2006), Malagasy tenrecs diversified into a wide variety of  
47 descendant species which convergently resemble distantly related  
48 insectivore mammals such as shrews (*Microgale* tenrecs), moles  
49 (*Oryzorictes* tenrecs) and hedgehogs (*Echinops* and *Setifer* tenrecs)  
50 (Eisenberg & Gould, 1969). These convergent resemblances are so great  
51 that tenrecs used to be considered part of the general "insectivore" clade  
52 and only molecular studies revealed their true phylogenetic affinities  
53 within the Afrotherian mammals (Stanhope et al., 1998).

54 Tenrecs are often cited as an example of an adaptively radiated family  
55 which exhibits exceptional morphological diversity (Soarimalala &  
56 Goodman, 2011; Olson & Goodman, 2003; Eisenberg & Gould, 1969).  
57 However, this apparent exceptional diversity has not been tested. Here we  
58 present the first quantitative test of patterns of phenotypic diversity in  
59 tenrecs and examine how morphological diversity in tenrecs compares to  
60 their closest relatives, the golden moles (Afrosoricida, Chrysochloridae).

61 We use disparity, the diversity of organic form (Foote, 1997; Wills et al.,  
62 1994; Erwin, 2007), to measure phenotypic variety within the two families.  
63 There is no single definition of disparity and it can be calculated in many  
64 ways including measures of morphospace occupation (e.g. Goswami et al.,  
65 2011; Brusatte et al., 2008) and rate-based approaches that assess the

66 amount of directed change away from an ancestor (O'Meara et al., 2006;  
67 Price et al., 2013). Here we focus on patterns of phenotypic variety in  
68 extant species rather than analysing the rate of diversity accumulation  
69 through time. Using the most complete morphological data set of tenrecs  
70 and golden moles to date we apply two dimensional geometric  
71 morphometrics (Rohlf & Marcus, 1993; Adams et al., 2013) to quantify  
72 variation in cranial and mandible morphologies as proxies for phenotypic  
73 diversity in the two families.

74 Our results indicate an overall trend of higher morphological diversity  
75 in tenrec compared to golden mole crania. However, most of these  
76 differences are not statistically significant, indicating that, with regards to  
77 cranial shape, tenrecs are not as phenotypically diverse as is often  
78 assumed. In contrast, we found significantly greater morphological  
79 disparity in golden mole mandibles compared to tenrecs, seemingly due  
80 to more variable posterior mandible morphologies in golden moles.

81 These findings cast doubt over whether the apparent phenotypic  
82 diversity within tenrecs should be considered to be truly exceptional.

## 83 **Materials and Methods**

### 84 **Morphological data collection**

85 One of us (SF) photographed cranial specimens of tenrecs and golden  
86 moles at the Natural History Museum London (NHML), the Smithsonian  
87 Institute Natural History Museum (SI), the American Museum of Natural  
88 History (AMNH), Harvard's Museum of Comparative Zoology (MCZ)  
89 and the Field Museum of Natural History, Chicago (FMNH). We

90 photographed the specimens with a Canon EOS 650D camera fitted with  
91 an EF 100mm f/2.8 Macro USM lens using a standardised procedure to  
92 minimise potential error (see supplementary material for details).

93 We collected pictures of the skulls in dorsal, ventral and lateral views  
94 (right side of the skull) and of the outer (buccal) side of the right  
95 mandibles. A full list of museum accession numbers and details for how  
96 to access the images can be found in the supplementary material.

97 In total we collected pictures from 182 skulls in dorsal view (148  
98 tenrecs and 34 golden moles), 173 skulls in ventral view (141 tenrecs and  
99 32 golden moles), 171 skulls in lateral view (140 tenrecs and 31 golden  
100 moles) and 182 mandibles in lateral view (147 tenrecs and 35 golden  
101 moles), representing 31 species of tenrec (out of the total 34 in the family)  
102 and 12 species of golden moles (out of a total of 21 in the family (Asher  
103 et al., 2010)). We used the taxonomy of Wilson and Reeder (2005)  
104 supplemented with more recent sources (IUCN, 2012; Olson, 2013) to  
105 identify our specimens.

106 We used a combination of both landmarks (type 2 and type 3,  
107 (Zelditch et al., 2012)) and semilandmarks to characterise the shapes of  
108 our specimens. Figure 1 shows our landmarks (points) and  
109 semilandmarks (outline curves) for the skulls in dorsal and ventral views  
110 and figure 2 shows the points and curves we used for lateral views of  
111 skulls and mandibles. Corresponding definitions of each of the landmarks  
112 can be found in the supplementary material.

113 We digitised all landmarks and semilandmarks in tpsDIG, version 2.17  
114 (Rohlf, 2013). We re-sampled the outlines to the minimum number of  
115 evenly spaced semilandmark points required to represent each outline

116 accurately (MacLeod, 2013, details in supplementary material). We used  
117 TPSUtil (Rohlf, 2012) to create sliders files (Zelditch et al., 2012) to define  
118 which points were semilandmarks. We conducted all subsequent analyses  
119 in R version 3.0.2 (R Core Team, 2014) within the geomorph package  
120 (Adams et al., 2013). We used the gpagen function to run a general  
121 Procrustes alignment (Rohlf & Marcus, 1993) of the landmark coordinates  
122 while sliding the semilandmarks by minimising procrustes distance  
123 (Bookstein, 1997). We used these Procrustes-aligned coordinates of all  
124 species to calculate average shape values for each species (n=43) which we  
125 then used for a principal components (PC) analysis with the  
126 plotTangentSpace function (Adams et al., 2013).

## 127 **Disparity calculations**

128 We calculated morphological disparity separately for golden moles and  
129 tenrecs in each of the morphological datasets. We used the PC axes which  
130 accounted for 95% of the cumulative variation to calculate four disparity  
131 metrics; the sum and product of the range and variance of morphospace  
132 occupied by each family (Brusatte et al., 2008; Foth et al., 2012; Ruta et al.,  
133 2013). We also calculated morphological disparity directly from the  
134 Procrustes-superimposed shape data based on the sum of the squared  
135 inter-landmark distances between the average shape of a species and the  
136 overall grand mean shape (SSqDist, Zelditch et al., 2012).

137 We used two approaches to test whether tenrecs have significantly  
138 different morphologies compared to golden moles. The first was a  
139 comparison of morphospace occupation between the two groups with non  
140 parametric MANOVAs (Anderson, 2001) to test whether tenrecs and

141 golden moles occupy significantly different areas of morphospace (e.g  
142 Serb et al., 2011; Ruta et al., 2013).

143 Secondly, we used pairwise permutation tests to test the null  
144 hypothesis that tenrecs and golden moles have equal disparity. If this  
145 hypothesis were true then the designation of each species as belonging to  
146 either tenrecs or golden moles should be arbitrary. Therefore we  
147 permuted the data by assigning family identities at random to each  
148 specimen and calculated the differences in disparity for each of the new  
149 family groupings. We repeated these permutations 1000 times to generate  
150 a null distribution of the expected differences in family disparity. We  
151 compared our observed (true) measures of the differences in disparity  
152 between tenrecs and golden moles to these permuted distributions to  
153 test whether the families had significantly different levels of disparity.

154 The majority of tenrec species (19 out of 31 in our data) are members  
155 of the *Microgale* (shrew-like) genus which is notable for its relatively low  
156 phenotypic diversity (Soarimalala & Goodman, 2011; Jenkins, 2003). The  
157 strong similarities among these species may mask signals of higher  
158 disparity among other tenrecs. Therefore we repeated our family-level  
159 comparisons of disparity with a reduced data set that excluded the  
160 *Microgale* so that we could compare disparity within the remaining 12  
161 tenrec species to disparity within the 12 species of golden moles.

## Results

### Morphological disparity in tenrecs and golden moles

Figure 3 depicts the morphospace plots derived from our principal components analyses of average Procrustes-superimposed shape coordinates for each species in our skull and mandible data respectively. We used the principal components axes which accounted for 95% of the cumulative variation ( $n = 7, 8, 8$  axes for the dorsal, ventral and lateral skull analyses respectively and  $n = 12$  axes for the mandibles) to calculate the disparity of each family.

Tenrecs and golden moles clearly have very different cranial and mandible morphologies: in each analysis, the families occupy significantly different areas of morphospace (npMANOVA, table 3). Our comparisons of disparity levels within each family yielded different trends for the skulls compared to the mandible analyses.

In our analyses of the three different views of the skulls, when disparity is calculated from principal component - based metrics there is an overall trend for tenrecs to have higher disparity than golden moles. However, none of these differences are statistically significant (table 1).

In contrast, when we calculated disparity based on the squared inter-landmark distances between the average shape of a species and the overall grand mean shape (Zelditch et al., 2012) then golden moles had significantly higher levels of disparity than tenrecs (table 1). These results indicate that golden moles are more distant from the overall mean shape in each of the analyses (farther from the (0,0) points in the PCA plots figure 3) which makes intuitive sense given that the overall meanshape in

each analysis will necessarily be biased towards the more species-rich tenrec family.

There is a less clear pattern from our analysis of disparity in the mandibles. Three of our five metrics indicate that golden moles have significantly higher disparity in the shape of their mandibles than tenrecs (table 1) although one metric (sum of ranges) indicated the opposite result.

The three curves at the back of the mandibles (figure 2) place a particular emphasis on shape variation in the posterior of the bone; the ramus, coronoid, condylar and angular processes. Therefore, higher disparity in golden mole mandibles compared to tenrecs could be driven by greater morphological variation in these structures. To test this idea, we repeated our morphometric analyses of the mandibles with a reduced data set of points; just the seven landmark points and one single curve at the base of the jaw between landmarks 1 and 7 (figure 2). When we compared familial disparity levels with this reduced data set we found that golden moles no longer had significantly higher disparity than tenrecs but rather there were some indications that the opposite was true (table 1).

## **Morphological disparity in non-*Microgale* tenrecs and golden moles**

We repeated our disparity comparisons with a subset of the tenrec specimens to remove the large and phenotypically similar *Microgale* tenrec genus. In this case we found that tenrecs have significantly higher disparity than golden moles when the skulls are analysed in lateral view (table 2). However, none of the other comparisons in any of the analyses were significant. Similarly, the trend in the main analysis for golden moles

212 to have significantly higher disparity measured as the sum of squared  
213 inter-landmark distances (table 1) was not repeated in this comparison of  
214 disparity in non-*Microgale* tenrecs and golden moles (table 2).

## 215 Discussion

216 Here we presented the first quantitative investigation of morphological  
217 disparity in tenrecs and our results suggest that phenotypic variation in  
218 tenrecs is not as exceptional as it first appears.

219 When we compared tenrecs' cranial morphologies to their closest  
220 relatives we found a trend towards higher disparity in tenrecs than in  
221 golden moles but none of these differences were significant. In contrast,  
222 the analyses of the mandibles indicated that golden moles have more  
223 disparate mandible shapes than tenrecs seemingly due to greater diversity  
224 within their posterior-mandible shapes.

225 It is evident that tenrecs are a diverse group, both phenotypically and  
226 ecologically. Body sizes of extant tenrecs span three orders of magnitude  
227 (2.5 to > 2,000g) which is a greater range than all other Families, and most  
228 Orders, of living mammals (Olson & Goodman, 2003). Within this vast  
229 size range there is striking phenotypic diversity, from the spiny *Echinops*,  
230 *Setifer* and striking *Hemicentetes* to the shrew-like *Microgale*. Furthermore,  
231 tenrecs inhabit a variety of ecological niches and habitats including  
232 terrestrial, arboreal, semi-aquatic and semi-fossorial forms (Soarimalala &  
233 Goodman, 2011). In contrast, although golden moles occupy a wide  
234 altitudinal, climatic and vegetational spectrum of habitats (Bronner, 1995),  
235 they are all fossorial species which, superficially at least, appear to be

236 less phenotypically diverse than tenrecs.

237       There is a danger when using sister taxa comparisons that a clade's  
238 diversity will be judged to be exceptional just because it is more variable  
239 than an exceptionally non-diverse sister taxa (Losos & Miles, 2002).  
240 However, we compared an apparently phenotypically diverse clade to a  
241 more uniform sister taxa yet our results do not indicate that tenrecs are  
242 more morphologically diverse than their closest relatives (table 1).

243       One apparent anomaly in our results is that we found opposite  
244 patterns of group dissimilarities in the analyses of skulls and mandibles.  
245 Our landmarks and curves for the mandibles (figure 2) include aspects of  
246 variation in the dentition but they focus particular attention on the  
247 ascending ramus (condyloid, condylar and angular processes). Therefore  
248 higher disparity in golden moles could reflect greater morphological  
249 variability in these posterior mandible structures. To test this idea we  
250 deleted the three semi-landmark curves around these structures and  
251 repeated our disparity analyses of mandibles using seven landmarks and  
252 just one curve at the base of the jaw. In this case we retrieved the opposite  
253 pattern than previously: tenrecs had higher morphological disparity than  
254 golden moles (see supplementary material). Therefore, our results  
255 indicate that golden moles have greater morphological variation in the  
256 posterior structures of their mandibles compared to tenrecs.

257       It proved impossible to position reliable landmarks on the  
258 corresponding mandibular articulation areas of the skull in lateral view  
259 (see supplementary). Therefore we could not test whether higher  
260 morphological disparity in the rami were correlated with associated  
261 morphological variety in the articulation areas of the skull.

262 Evidence of exceptional morphological diversity is one criterion for  
263 designating a clade as an adaptive radiation (Losos & Mahler, 2010) and  
264 our analyses are the first measures of morphological diversity within  
265 tenrecs, a group which is commonly cited as an example of an adaptive  
266 radiation (Olson, 2013). However, describing phenotypic divergence as the  
267 product of an adaptive radiation requires exceptional morphological  
268 diversity in traits which have specific and proven adaptive significance  
269 (Losos & Mahler, 2010). We have not included any measures of the  
270 "adaptiveness" of cranial shape in our analyses and therefore our analyses  
271 should not be considered to be an explicit test of whether tenrecs are an  
272 adaptive radiation or not.

273 The evolution of cranial shape (both upper skull and mandible),  
274 particularly dental morphology, has obvious correlations with dietary  
275 specialisations (REFS) and occupation of specific ecological niches (REFS).  
276 Considering the wide ecological diversity of our study species;  
277 semi-fossorial, arboreal, terrestrial and semi-aquatic tenrecs (Soarimalala  
278 & Goodman, 2011) we think that it is reasonable to expect that this variety  
279 should be reflected in skull morphology. Future work should focus on  
280 explicit measures of the "adaptiveness" and functional importance of  
281 tenrec cranial and post-cranial morphologies to understand the  
282 significance of morphological diversity within the family (e.g. Mahler  
283 et al., 2010).

284 Studies of morphological disparity are inevitably constrained to  
285 measure diversity within specific traits rather than overall phenotypes  
286 (Roy & Foote, 1997). Here we focused on cranial morphology, traits which  
287 are commonly used to delineate species boundaries (REFS) or for  
288 cross-taxonomic comparative studies of phenotypic (dis)similarities

289 (REFS). Disparity calculations based on skull shape can yield similar  
290 results compared to analyses of whole-skeleton discrete characters and  
291 limb proportion data sets (Foth et al., 2012).

292 However, we would need to extend our analyses to other  
293 morphological proxies of phenotype to test whether the cranial  
294 morphological disparity patterns presented here are indicative of overall  
295 differences in phenotypic diversity in tenrecs and golden moles.

296 These results highlight the importance of applying quantitative  
297 methods to testing our assumptions about adaptively radiated groups.

298 These analyses represent the first attempt to find evidence to support  
299 the common claim that tenrecs are an adaptive radiation. Future work  
300 will develop our results by expanding the analyses to non-cranial  
301 morphology and also measures of ecological diversity. However, our  
302 current results provide a clear indication that phenotypic variety within  
303 tenrecs is perhaps not as exceptional as it first seems and therefore their  
304 designation as an adaptive radiation may need to be re-considered.

## 415 **List of Figures**

|     |   |  |    |
|-----|---|--|----|
| 416 | 1 | Diagram of the landmarks and curves for the skulls in dorsal |    |
| 417 |   | and ventral views . . . . .                                  | 21 |
| 418 | 2 | Diagrams of the landmarks and curves used for lateral views  |    |
| 419 |   | of skulls and mandibles . . . . .                            | 22 |
| 420 | 3 | Principal components plots of the morphospaces occupied      |    |
| 421 |   | by tenrecs and golden moles . . . . .                        | 23 |

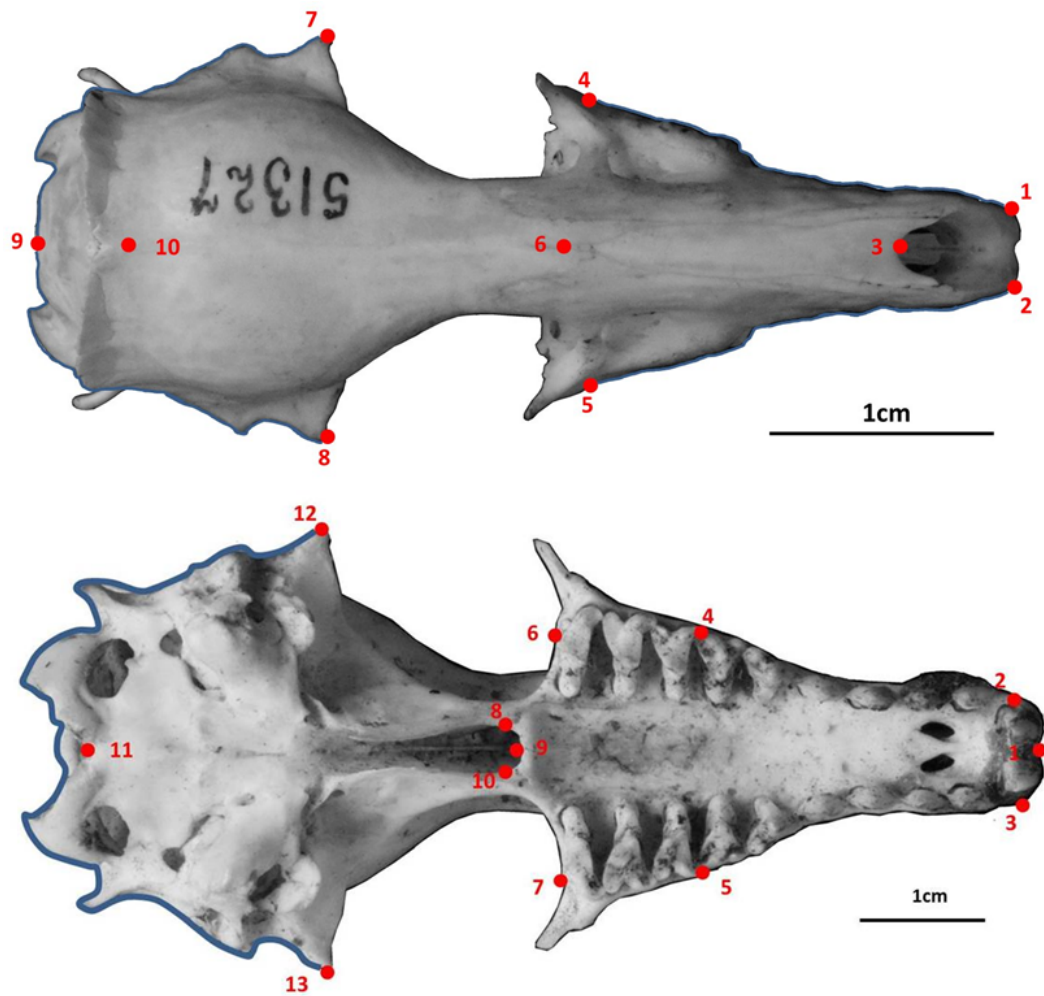

Figure 1: Landmarks (red points) and curves (blue lines) used to capture the morphological shape of skulls in dorsal and ventral views respectively. Curves were re-sampled to the same number of evenly-spaced points. Descriptions of the curves and landmarks are in the supplementary material. The specimens belong to two different *Potamogale velox* (Tenrecidae) skulls: accession number AMNH 51327 for the dorsal picture and NHML 1934.6.16.2 for the ventral picture

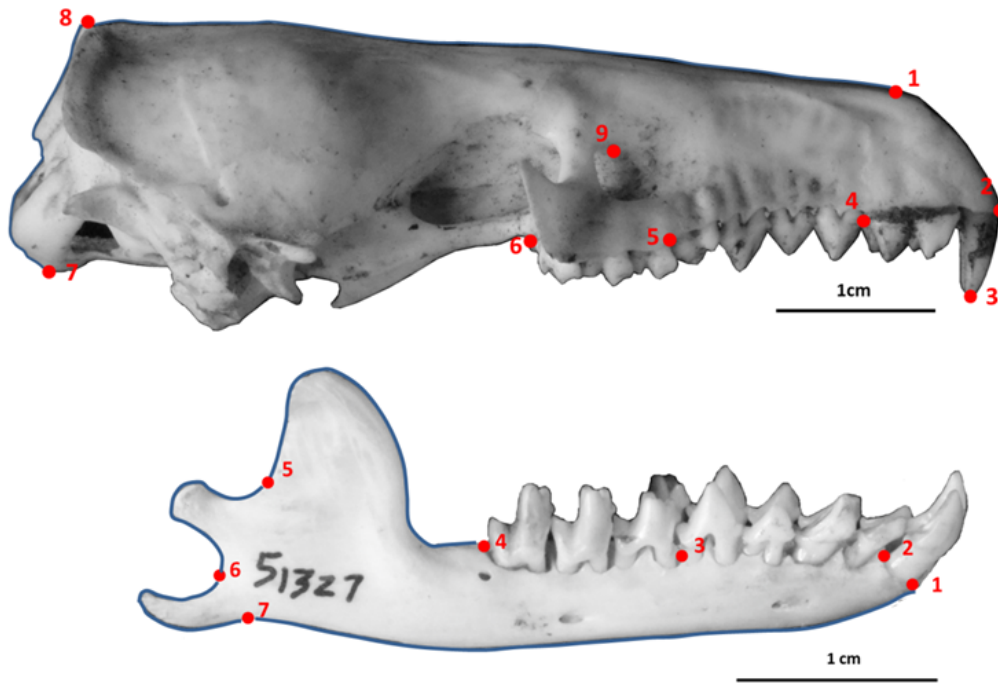

Figure 2: Landmarks (red points) and curves (blue lines) used to capture the morphological shape of lateral views of skulls and mandibles respectively. Curves were re-sampled to the same number of evenly-spaced points. Descriptions of the curves and landmarks are in the supplementary material. The specimens belong to two different *Potamogale velox* (Tenrecidae) skulls: accession number AMNH 51327 for the dorsal picture and NHML 1934.6.16.2 for the ventral picture

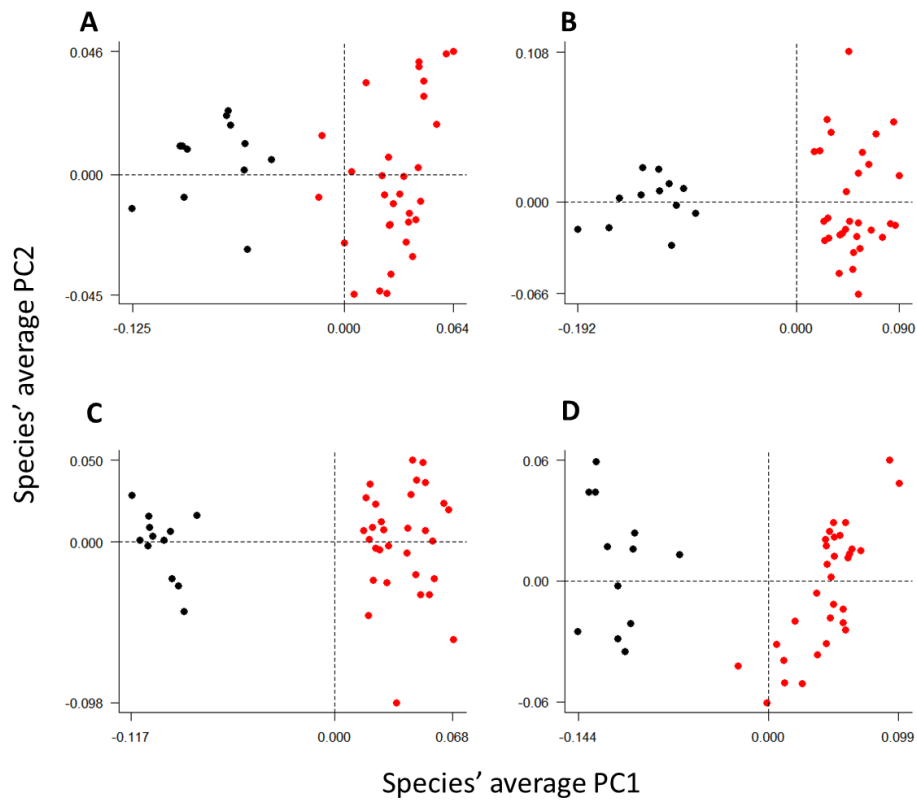

Figure 3: Principal components plots of the morphospaces occupied by tenrecs (red,  $n=31$  species) and golden moles (black,  $n=12$ ) for the skulls: dorsal (A), ventral (B), lateral (C) and mandibles (D) analyses. Axes are PC1 and PC2 of the average scores from a PCA analysis of mean Procrustes shape coordinates for each species.

## 422 List of Tables

|     |   |  |    |
|-----|---|--|----|
| 423 | 1 | Summary of disparity comparisons between tenrecs and golden    |    |
| 424 |   | moles . . . . .  | 25 |
| 425 | 2 | Summary of disparity comparisons between non- <i>Microgale</i> |    |
| 426 |   | tenrecs and golden moles . . . . .                             | 26 |
| 427 | 3 | Summary of npMANOVA comparisons of morphospace oc-             |    |
| 428 |   | cupation for tenrecs and golden moles . . . . .                | 27 |

Table 1: Summary of disparity comparisons between tenrecs (T) and golden moles (G) for each of our data sets(rows) and five disparity metrics (columns). "Mandibles:one curve" refers to our shape analysis of mandibles excluding the three curves around the posterior structures of jaw (figure 2). Significant differences are highlighted in bold with the corresponding p value in brackets. Disparity metrics are; sum of variance, product of variance, sum of ranges, product of ranges and sum of squared distances among species.

| <b>Disparity metric</b> | <b>SumVar</b> | <b>ProdVar</b>         | <b>SumRange</b>        | <b>ProdRange</b>       | <b>SSqDist</b>     |
|-------------------------|---------------|------------------------|------------------------|------------------------|--------------------|
| Skulls dorsal           | T>G           | T>G                    | T>G                    | T>G                    | <b>G&gt;T* (0)</b> |
| Skulls lateral          | T>G           | T>G                    | T>G                    | T>G                    | <b>G&gt;T* (0)</b> |
| Skulls ventral          | T>G           | G>T                    | T>G                    | T>G                    | <b>G&gt;T* (0)</b> |
| Mandibles               | G>T           | <b>G&gt;T* (0.008)</b> | <b>T&gt;G* (0.025)</b> | <b>T&gt;G* (0.009)</b> | <b>T&gt;G* (0)</b> |
| Mandibles               | G>T           | G>T                    | T>G                    | T>G                    | <b>T&gt;G* (0)</b> |

Table 2: Summary of disparity comparisons between non-*Microgale* tenrecs (T) and golden moles (G) for each of our data sets(rows) and five disparity metrics (columns). Significant differences are highlighted in bold with the corresponding p value in brackets. Disparity metrics are; sum of variance, product of variance, sum of ranges, product of ranges and sum of squared distances among species.

| Disparity metric | SumVar       | ProdVar | SumRange               | ProdRange             | SSqDist                |
|------------------|--------------|---------|------------------------|-----------------------|------------------------|
| Skulls dorsal    | T>G          | T>G     | T>G                    | T>G                   | T>G                    |
| Skulls lateral   | T>G* (0.014) | T>G     | <b>T&gt;G* (0.001)</b> | <b>T&gt;G*(0.003)</b> | <b>G&gt;T* (0.014)</b> |
| Skulls ventral   | T>G          | T>G     | T>G                    | T>G                   | T>G                    |
| Mandibles        | T>G          | G>T     | T>G                    | G>T                   | G>T                    |

Table 3: Summary of the npMANOVA comparisons of morphospace occupation for tenrecs and golden moles in each of the four analyses (three views of skulls and mandibles). In each case the two families occupy significantly different areas of morphospace.

| <b>Analysis</b> | <b>F</b> | <b>R<sup>2</sup></b> | <b>p value</b> |
|-----------------|----------|----------------------|----------------|
| Skulls dorsal   | 66.02    | 0.62                 | 0.001          |
| Skulls ventral  | 100.74   | 0.71                 | 0.001          |
| Skulls lateral  | 75.07    | 0.65                 | 0.001          |
| Mandibles       | 59.34    | 0.59                 | 0.001          |
